Abstract

Background: Patients with highly mutated tumors, such as melanoma or smoking-related lung cancer, have higher rates of response to immune checkpoint blockade therapy, perhaps due to increased neoantigen expression. Many chemotherapies including platinum compounds are known to be mutagenic, but the impact of standard treatment protocols on mutational burden and resulting neoantigen expression in most human cancers is unknown.

Methods: We sought to quantify the effect of chemotherapy treatment on computationally predicted neoantigen expression for high grade serous ovarian carcinoma (HGSC) patients enrolled in the Australian Ovarian Cancer Study. This 92-patient series includes 30 chemotherapy-exposed relapse samples, 14 of which are matched with an untreated sample from the same patient. Our approach integrates tumor whole genome and RNA sequencing with class I MHC binding prediction and mutational signatures of chemotherapy exposure extracted from preclinical studies of chemotherapy-exposed *C. Elegans* and *G. Gallus* cells.

Results: Relapse samples collected after chemotherapy harbored a median of 78% more expressed neoantigens than untreated primary samples, a figure that combines the effects of chemotherapy and other processes operative during relapse. Neoadjuvant-treated primary samples showed no detectable increase over untreated samples. The contribution from chemotherapy-associated signatures was small, accounting for a mean of 5% (range 0–16) of the expressed neoantigen burden in relapse samples. In both treated and untreated samples, most neoantigens were attributed to COSMIC *Signature* (3), associated with BRCA disruption, *Signature* (1), associated with a slow mutagenic process active in healthy tissue, and *Signature* (8), of unknown etiology.

Conclusion: Relapsed HGSC tumors harbor more predicted expressed neoantigens than primary samples, but the increase is due to pre-existing mutational processes, not direct mutagenesis from chemotherapy. Our analyses are based on sequencing of bulk samples and do not account for neoantigens present in small populations of cells.

Keywords: neoantigen; mutational signature; chemotherapy

Background

Many chemotherapies including platinum compounds [1], cyclophosphamide [2], and etoposide [3] exert their effect through DNA damage, and recent studies have found evidence for chemotherapy-induced mutations in post-treatment acute myeloid leukaemia [4], glioma [5], and esophageal adenocarcinoma [6]. Successful development of immune checkpoint-mediated therapy [7] has focused attention on

Table 1 Number of samples by tissue and chemotherapy exposure. Parentheses indicate chemotherapy-treated samples with a patient-matched primary/untreated sample.

the importance of T cell responses to somatic mutations in coding genes that generate neoantigens [8]. Studies based on bulk-sequencing of tumor samples followed by computational peptide-class I MHC affinity prediction [9] have suggested that tumors with more mutations and predicted mutant MHC I peptide ligands are more likely to respond to checkpoint blockade immunotherapy [10, 11]. Ovarian cancers fall into an intermediate group of solid tumors in terms of mutational load present in pre-treatment surgical samples[12]. However, the effect of standard chemotherapy regimens on tumor mutation burden and resulting neoantigen expression in ovarian cancer is poorly understood.

Investigators associated with the Australian Ovarian Cancer Study (AOCS) performed whole genome and RNA sequencing of 79 pre-treatment and 35 post-treatment cancer samples from 92 HGSC patients, including 12 patients with both pre- and post-treatment samples [13]. The samples were obtained from solid tissue resections, autopsies, and ascites drained to relieve abdominal distension. Treatment regimes varied but primary treatment always included platinum-based chemotherapy. In their analysis, Patch et al. reported that post-treatment samples harbored more somatic mutations than pre-treatment samples and exhibited evidence of chemotherapy-associated mutations. Here we extend these results by quantifying the mutations and predicted neoantigens attributable to chemotherapy-associated mutational signatures. We find that, while neoantigen expression increases after treatment and relapse, only a small part of the increase is due to mutations associated with chemotherapy signatures.

Methods

Clinical sample information

We grouped the AOCS samples into three sets — “primary/untreated,” “primary/treated,” and “relapse/treated” — according to collection time point and chemotherapy exposure (Table 1). The primary/untreated group consists of 75 primary debulking surgical samples and 4 samples of drained ascites. The primary/treated group consists of 5 primary debulking surgical samples obtained from patients pretreated with chemotherapy prior to surgery (neoadjuvant chemotherapy). The relapse/treated group consists of 24 relapse or recurrence ascites samples, 5 metastatic samples obtained in autopsies of two patients, and 1 solid tissue relapse surgical sample, all of which were obtained after prior exposure to one or more lines of chemotherapy. In summary, these groupings yield 79 primary/untreated samples,

15 primary/treated samples, and 30 relapse/treated samples. Specimen and clinical¹
 2 information for each sample is listed in Additional File 1. ²

3 Independent of treatment, ascites samples trend toward more detected mutations,³
 4 perhaps due to increased intermixing of clones. We therefore stratified by tissue type⁴
 5 (solid tumor or ascites) when comparing the mutation and neoantigen burdens of⁵
 6 pre- and post-treatment samples. As some patients provided multiple samples of⁶
 7 the same type, we reweighted the samples so each patient contributes equally to⁷
 8 these comparisons. ⁸

10 Mutation calls ¹⁰

11 We analyzed the mutation calls published by Patch et al. [13] (Additional File 2).¹¹
 12 DNA and RNA sequencing reads were downloaded from the European Genome-¹²
 13 phenome Archive under accession EGAD00001000877. Adjacent SNVs from the¹³
 14 same patient were combined to form multinucleotide variants (MNVs). ¹⁴
 15 We considered a mutation to be present in a sample if it was called for the patient¹⁵
 16 and more than 5 percent of the overlapping reads and at least 6 reads total supported¹⁶
 17 the alternate allele. We considered a mutation to be expressed if there were 3 or¹⁷
 18 more RNA reads supporting the alternate allele. In the analysis of paired pre- and¹⁸
 19 post-treatment samples from the same donors, we defined a mutation as unique to¹⁹
 20 the post-treatment sample if the pre-treatment sample contained greater than 30²⁰
 21 reads coverage and no variant reads at the site. ²¹

23 Variant annotation, HLA typing, and MHC binding prediction ²³

24 Protein coding effects were predicted using Varcode (manuscript in preparation,²⁴
 25 <https://github.com/hammerlab/varcode>). All transcripts overlapping each muta-²⁵
 26 tion were considered, and the transcript with the most disruptive effect was selected²⁶
 27 using a prioritization similar to other tools (from highest priority: frameshift, loss of²⁷
 28 stop codon, insertion or deletion, substitution). In the case of frameshift mutations,²⁸
 29 all downstream peptides generated up to a stop codon were considered potential²⁹
 30 neoantigens. ³⁰

31 HLA typing was performed using a consensus of seq2HLA [14] and OptiType [15]³¹
 32 across the samples for each patient (Additional File 3). ³²

33 Class I MHC binding predictions were performed for peptides of length 8–11 using³³
 34 NetMHCpan 2.8 [16] with default arguments (predicted neoantigens are listed in³⁴
 35 Additional File 2). ³⁵

36 Mutational signatures ³⁶

37 The use of mutational signatures is necessary because it is not possible to dis-³⁷
 38 tinguish chemotherapy-induced mutations from temporal effects when comparing³⁸
 39 primary and relapse samples by mutation count alone. A mutational signature as-³⁹
 40 cribes a probability to each of the 96 possible single-nucleotide variants, where a⁴⁰
 41 variant is defined by its reference base pair, alternate base pair, and base pairs im-⁴¹
 42 mediately adjacent to the mutation. Signatures have been associated with exposure⁴²
 43 to particular mutagens, age related DNA changes, and disruption of DNA damage⁴³
 44 repair pathways due to somatic mutations or germline risk variants in melanoma,⁴⁴
 45 breast, lung and other cancers [17], and provide a means of identifying the con-⁴⁵
 46 tribution that chemotherapy may make to the mutations seen in post-treatment⁴⁶

¹samples. For example, the chemotherapy temozolomide has been shown to induce¹
²mutations consisting predominantly of $C \rightarrow T$ (equivalently, $G \rightarrow A$) transitions²
³at CpC and CpT dinucleotides [5]. To perform deconvolution, the single nucleotide³
⁴variants (SNVs) observed in a sample are tabulated by trinucleotide context, and⁴
⁵a combination of signatures, each corresponding to a mutagenic process, is found⁵
⁶that best explains the observed counts. Mutational signatures may be discovered *de*⁶
⁷*novo* from large cancer sequencing projects but for smaller studies it is preferable⁷
⁸to deconvolve using known signatures [18].⁸

⁹ The Catalogue Of Somatic Mutations In Cancer (COSMIC) Signature Resource⁹
¹⁰curates 30 signatures discovered in a pan-cancer analysis of untreated primary tissue¹⁰
¹¹samples. While signatures for exposure to the carboplatin/paclitaxel combination¹¹
¹²that is standard first line therapy in ovarian cancer have not been established,¹²
¹³two recent reports provide data on mutations detected in cisplatin-exposed *C. El*¹³
¹⁴*egans* [19] and a *G. Gallus* cell line exposed to several chemotherapies including¹⁴
¹⁵cisplatin, cyclophosphamide, and etoposide [20]. As cisplatin is thought to induce¹⁵
¹⁶the same DNA adducts as carboplatin, we reasoned that the mutational signatures¹⁶
¹⁷of these related compounds are likely similar [21]. In the AOCS cohort, 28 patients¹⁷
¹⁸with post-treatment samples were treated with carboplatin, four with cisplatin,¹⁸
¹⁹eight with cyclophosphamide, and one with etoposide.¹⁹

²⁰ From the SNVs identified in the animal models, we defined two signatures for²⁰
²¹cisplatin, a signature for cyclophosphamide, and a signature for etoposide (Fig-²¹
²²ures S1 and S2). As both studies sequenced replicates of chemotherapy-treated²²
²³and untreated (control) samples, identifying a mutational signature associated with²³
²⁴treatment required splitting the mutations observed in the treated group into back-²⁴
²⁵ground and treatment effects. We did this using a Bayesian model for each study²⁵
²⁶and chemotherapy drug separately.²⁶

²⁷ Let $C_{i,j}$ be the number of mutations observed in experiment i for mutational trin-²⁷
²⁸ucleotide context $0 \leq j < 96$. Let $t_i \in \{0, 1\}$ be 1 if the treatment was administered²⁸
²⁹in experiment i and 0 if it was a control. We estimate the number of mutations²⁹
³⁰in each context arising due to background (non-treatment) processes B_j and the³⁰
³¹number due to treatment T_j according to the model:³¹

$$C_{i,j} \sim \text{Poisson}(B_j + t_i T_j)$$

³⁴ We fit this model using Stan [22] with a uniform (improper) prior on the entries³⁴
³⁵of B and T . The treatment-associated mutational signature N was calculated from³⁵
³⁶a point estimate of T as:³⁶

$$N_j = \left(\frac{T_j}{\sum_{j'} T_{j'}} \right) \left(\frac{h_j}{m_j} \right)$$

⁴¹ where h_j and m_j are the number of times the reference trinucleotide j occurs in⁴¹
⁴²the human and preclinical model (*C. Elegans* or *G. Gallus*) genomes, respectively.⁴²

⁴³ Signature deconvolution was performed with the deconstructSigs[18] package us-⁴³
⁴⁴ing the 30 mutational signatures curated by COSMIC [23] extended to include the⁴⁴
⁴⁵putative chemotherapy-associated signatures (Additional Files 4 and 5). When es-⁴⁵
⁴⁶tablishing whether a signature was detected in a sample, we applied the 6% cutoff⁴⁶

¹recommended by the authors of the deconstructSigs package. Signatures assigned¹
²weights less than this threshold in a sample were considered undetected.²

³To estimate the number of SNVs and neoantigens generated by a signature, for³
⁴each mutation in the sample we calculated the posterior probability that the sig-⁴
⁵nature generated the mutation, as described below. The sum of these probabilities⁵
⁶gives the expected number of SNVs attributable to each signature. For neoantigens,⁶
⁷we weighted the terms of this sum by the number of neoantigens generated by each⁷
⁸mutation.⁸

⁹Suppose a mutation occurs in context j and sample i . We calculate $\Pr[s | j]$, the⁹
¹⁰probability that signature s gave rise to this mutation, using Bayes' rule:¹⁰

$$\Pr[s | j] = \frac{\Pr[j | s] \Pr[s]}{\sum_{s'} \Pr[j | s'] \Pr[s']} = \frac{H_{s,j} D_{i,s}}{\sum_{s'} H_{s',j} D_{i,s'}} \quad (1)$$

¹⁵where $D_{i,s}$ is the result matrix from deconstructSigs, giving the contribution of¹⁵
¹⁶signature s to sample i , and $H_{s,j}$ is the weight for signature s on mutational context¹⁶
¹⁷ j . For each chemotherapy-associated signature, $H_{s,j}$ is given by N_j above. For the¹⁷
¹⁸other signatures it is defined in the COSMIC Signature Resource.¹⁸

¹⁹For treated samples with a pre-treatment sample available from the same patient,¹⁹
²⁰we deconvolved signatures for both the full set of mutations and for the mutations²⁰
²¹detected only after treatment. When calculating $\Pr[s | j]$ for these samples, for each²¹
²²mutation we selected the appropriate deconvolution matrix $D_{i,s}$ based on whether²²
²³the mutation was unique to the post-treatment sample.²³

²⁵Results²⁵

²⁶Cisplatin and cyclophosphamide mutational signatures correlate with clinical treatment²⁶
²⁷We identified mutational signatures for cisplatin, cyclophosphamide, and etoposide²⁷
²⁸from the *G. Gallus* cell line data (Figure S1), as well as a second cisplatin signature²⁸
²⁹from experiments in *C. Elegans* (Figure S2). The two cisplatin signatures were not²⁹
³⁰identical. Both signatures placed most probability mass on $C \rightarrow A$ mutations, but³⁰
³¹differed in preference for the nucleotides adjacent to the mutation. The *G. Gallus*³¹
³²signature was relatively indifferent to the 5' base and favored a 3' cytosine, whereas³²
³³the *C. Elegans* signature was specific for a 5' cytosine and a 3' pyrimidine. The³³
³⁴*G. Gallus* cisplatin signature was closest in cosine distance to COSMIC Signature³⁴
³⁵(24) Aflatoxin, Signature (4) Smoking, and Signature (29) Chewing tobacco, all as-³⁵
³⁶sociated with guanine adducts. The *C. Elegans* cisplatin signature was similar to³⁶
³⁷Signature (4) Smoking, Signature (20) Mismatch repair, and Signature (14) Un-³⁷
³⁸known. The *G. Gallus* cyclophosphamide signature favored $T \rightarrow A$ and $C \rightarrow T$ ³⁸
³⁹mutations and was most similar to COSMIC Signatures (25), (8), and (5), all of³⁹
⁴⁰unknown etiology. The *G. Gallus* etoposide signature distributed probability mass⁴⁰
⁴¹nearly uniformly across mutation contexts and was most similar to COSMIC Sig-⁴¹
⁴²nature (5) Unknown, Signature (3) BRCA, and Signature (16) Unknown. Overall,⁴²
⁴³the chemotherapy signatures were no closer to any COSMIC signatures than the⁴³
⁴⁴two most similar COSMIC signatures (Signature (12) Unknown and Signature (26)⁴⁴
⁴⁵Mismatch repair) are to each other, suggesting that deconvolution could in principle⁴⁵
⁴⁶distinguish their contributions.⁴⁶

¹ We performed signature deconvolution on each sample's SNVs (top and middle¹
² of Figures S3 and S4). Detection of the cyclophosphamide signature at the 6%²
³ threshold was associated with clinical cyclophosphamide treatment (Bonferroni-³
⁴ corrected Fischer's exact test $p = 0.004$), occurring in 4/10 samples taken after cy-⁴
⁵ clophosphamide treatment, 2/79 pre-treatment samples, and 2/25 samples exposed⁵
⁶ to chemotherapies other than cyclophosphamide. In contrast, the two cisplatin sig-⁶
⁷ natures were found in no samples, and the etoposide signature was found only in⁷
⁸ four pre-treatment samples.⁸

⁹ For better sensitivity, we next focused on the 14 relapse/treated samples from⁹
¹⁰ the 12 patients with both pre- and post-treatment samples. For each patient, we¹⁰
¹¹ extracted the mutations that had evidence exclusively in the treated samples. Of¹¹
¹² 206,766 SNVs in the post-treatment samples for these patients, 93,986 (45%) satis-¹²
¹³ fied our filter and were subjected to signature deconvolution (Figure 1, bottom of¹³
¹⁴ Figures S3 and S4). Within this subgroup, the *G. gallus* cisplatin signature was iden-¹⁴
¹⁵ tified only in the two samples taken after cisplatin therapy, a significant association¹⁵
¹⁶ ($p = 0.04$). The *C. Elegans* cisplatin signature was detected in no samples, and the¹⁶
¹⁷ cyclophosphamide signature was detected in 3/6 cyclophosphamide-treated sam-¹⁷
¹⁸ ples, but, unexpectedly, also in 6/8 non-cyclophosphamide-treated samples. These¹⁸
¹⁹ included the two post-treatment samples in which the signature was detected in the¹⁹
²⁰ earlier analysis plus four additional samples. COSMIC Signature (3) BRCA and²⁰
²¹ Signature (8) Unknown etiology were detected in 14/14 and 9/14 post-treatment²¹
²² samples, respectively, but Signature (1) Age was absent, consistent with its associ-²²
²³ ation with a slow mutagenic process operative before oncogenesis.²³

²⁴ In summary, the mutational signatures for cisplatin and cyclophosphamide ex-²⁴
²⁵ tracted from experiments of a *G. Gallus* cell line showed significant but inexact²⁵
²⁶ associations with clinical chemotherapy exposure.²⁶

²⁸ Neoantigen burden increases at relapse²⁸

²⁹ Across the cohort, we identified 17,689 mutated peptides predicted to bind autol-²⁹
³⁰ ogous MHC class I with affinity 500nm or tighter [24]. All but 21 (0.12%) of these³⁰
³¹ predicted neoantigens were private to a single patient (shared neoantigens are listed³¹
³² in Additional File 6).³²

³³ Relapse/treated samples harbored a median 78% more expressed neoantigens than³³
³⁴ primary/untreated samples (weighted mean of stratum-specific estimates). Specif-³⁴
³⁵ ically, solid tissue relapse samples harbored a median of 71% (bootstrap 95% CI³⁵
³⁶ 23–123) more mutations, 107% (32–187) more neoantigens, and 72% (16–137) more³⁶
³⁷ expressed neoantigens than primary/untreated solid tissue samples (Figure 2), all³⁷
³⁸ significant increases (Mann-Whitney $p < 0.05$ for each of the three tests). A sim-³⁸
³⁹ ilar trend was observed for ascites samples. Relapse/treated ascites samples har-³⁹
⁴⁰ bored 32% (14–51), 55% (10–118), and 83% (22–178) more mutations, neoanti-⁴⁰
⁴¹ gens, and expressed neoantigens than primary/untreated ascites samples, respec-⁴¹
⁴² tively ($p = 0.07, 0.10, 0.05$ for the three tests). This trend was also apparent in⁴²
⁴³ a comparison of paired samples from the same donors (Figure S5). Among re-⁴³
⁴⁴ lapse/treated samples, the number of lines of chemotherapy and the time elapsed⁴⁴
⁴⁵ between chemotherapy and sample acquisition did not show a significant correlation⁴⁵
⁴⁶ (Figure S6). TODO⁴⁶

¹ In contrast, primary/treated samples, which were exposed to neoadjuvant¹
² chemotherapy (NACT) prior to surgery, did not exhibit increased numbers of muta-²
³ tions, neoantigens, or expressed neoantigens, and in fact trended toward decreased³
⁴ expressed neoantigen burden. The five primary/treated samples, all from solid tis-⁴
⁵ sue resections, harbored a median of 16 (9–89) expressed neoantigens compared to⁵
⁶ the median of 44 (39–60) observed in primary/untreated solid tissue samples, due to⁶
⁷ both fewer neoantigens in the DNA (median of 85 (36–306) vs. 130 (108–150)) and a⁷
⁸ lower rate of expression (median 19 (14–37) vs. 39 (36–42) percent of neoantigens).⁸
⁹ This trend did not reach significance (Mann-Whitney $p = 0.08$), and will require⁹
¹⁰ larger cohorts to assess.¹⁰

¹²Chemotherapy signatures weakly contribute to neoantigen burden at relapse¹²

¹³ While we cannot determine with certainty whether any particular mutation was¹³
¹⁴ chemotherapy-induced, we can estimate the fraction of mutations and neoantigens¹⁴
¹⁵ attributable to each signature in a sample (Figures 3 and S7).¹⁵

¹⁶ Similarly to results reported by Patch et al., the most prevalent mutational signa-¹⁶
¹⁷ tures in this cohort were COSMIC *Signature (3)*, associated with BRCA disruption,¹⁷
¹⁸ *Signature (8)*, of unknown etiology, and *Signature (1)*, associated with spontaneous¹⁸
¹⁹ deamination of 5-methylcytosine, a slow process active in healthy tissue that cor-¹⁹
²⁰ relates with age (Figure S3 top and middle). These signatures together accounted²⁰
²¹ for a median of 67% (95% CI 66–69) of mutations, 58% (56–61) of neoantigens, and²¹
²² 68% (67–71) expressed neoantigens across samples. These rates did not substantially²²
²³ differ with chemotherapy treatment.²³

²⁴ The chemotherapy signatures accounted for a small but detectable part of the²⁴
²⁵ increased neoantigen burden of relapse samples. In primary/untreated samples,²⁵
²⁶ which indicate the background rate of chance attribution, chemotherapy muta-²⁶
²⁷ tional signatures accounted for a mean of 2% of the mutations (range 0–8), 2%²⁷
²⁸ (0–7) of the neoantigens, and 2% (0–8) of the expressed neoantigens. In each of the²⁸
²⁹ five primary/treated samples, less than 1% of the mutation, neoantigen, and ex-²⁹
³⁰ pressed neoantigen burdens were attributed to chemotherapy signatures. For the re-³⁰
³¹ lapse/treated samples, chemotherapy signatures accounted for a mean of 6% (range³¹
³² 0–21) of the mutations, 5% (0–15) of the neoantigens, and 5% (0–16) of the expressed³²
³³ neoantigens. The highest attribution to chemotherapy signatures occurred in sample³³
³⁴ AOCS-092-3-3, a relapse/treated sample from a patient who received two lines of³⁴
³⁵ carboplatin and three lines of cisplatin, the most in the cohort. For this sample, 21%³⁵
³⁶ (or approximately 3,200 of 15,491) of the SNVs, 15% (9 of 61) of the neoantigens,³⁶
³⁷ and 16% (5 of 30) of the expressed neoantigens were attributed to chemotherapy³⁷
³⁸ signatures. Despite the substantial number of chemotherapy-signature mutations,³⁸
³⁹ this sample had an³⁹

⁴⁰ Signature deconvolution considers only SNVs, but studies of platinum-induced⁴⁰
⁴¹ mutations have also reported increases in the rate of dinucleotide variants and indels.⁴¹
⁴² Indeed, we observed more MNVs overall and specifically the platinum-associated⁴²
⁴³ MNVs $CT \rightarrow AC$ and $CA \rightarrow AC$ reported by Meier et al. [19] in treated patients⁴³
⁴⁴ in both absolute count and as a fraction of mutational burden ($p < 10^{-6}$ for all⁴⁴
⁴⁵ tests). Sample AOCS-092-3-3, previously found to have the most chemotherapy-⁴⁵
⁴⁶ signature SNVs, also had the most platinum-associated dinucleotide variants and⁴⁶

¹the second-most MNVs overall. This sample harbored 59 $CT \rightarrow AC$ or $CA \rightarrow AC$ ¹
²mutations, compared to a mean of 3.2 (2.2–4.4) across all samples. Treated samples²
³also harbored more indels in terms of absolute count ($p = 10^{-4}$). Overall, while³
⁴MNVs and indels generate more neoantigens per mutation than SNVs, they are⁴
⁵rare, comprising less than 3% of the mutational burden and 13% of the neoantigens⁵
⁶in every sample (Figure 3), making it unlikely that chemotherapy-induced MNVs⁶
⁷and indels have a large impact on neoantigen burden.⁷

⁹Discussion⁹

¹⁰In this analysis of neoantigens predicted from DNA and RNA sequencing of ovarian¹⁰
¹¹cancer tumors and ascites samples, relapse samples obtained after chemotherapy¹¹
¹²exposure had a median of 78% more expressed neoantigens than untreated primary¹²
¹³samples. However, putative chemotherapy mutational signatures accounted for no¹³
¹⁴more than 16% of the expressed neoantigen burden in any sample. Most of the¹⁴
¹⁵increase was instead attributable to mutagenic processes already at work in the pri-¹⁵
¹⁶mary samples, including COSMIC *Signature (3) BRCA* and *Signature (8) Unknown*¹⁶
¹⁷*etiology*.¹⁷

¹⁸These results are consistent with a model in which outgrowth of a subclone follow-¹⁸
¹⁹ing surgery and adjuvant chemotherapy brings many mutations previously confined¹⁹
²⁰to a small number of cells to population levels detectable by bulk sequencing. In²⁰
²¹such a model, it is not the direct mutagenic effect of the treatment that increases²¹
²²the mutational burden, but rather the indirect effect of creating a population bot-²²
²³tleneck. Consistent with this interpretation, NACT-treated samples, which were²³
²⁴exposed to chemotherapy as large tumors and for a short duration (typically 3 cy-²⁴
²⁵cles), did not show increased mutation or neoantigen burden over untreated samples²⁵
²⁶and had very few mutations attributed to chemotherapy.²⁶

²⁷Clinically, while recurrent tumors may be expected to harbor more potential²⁷
²⁸neoantigens, our results suggest it would be difficult to rationally increase neoanti-²⁸
²⁹gen burden through manipulation of chemotherapy dosage, as even the most heavily²⁹
³⁰treated patients in this cohort show only a modest number chemotherapy-induced³⁰
³¹neoantigens. As immunotherapy trials in ovarian cancer have been in the setting of³¹
³²heavily pre-treated recurrent disease and yet have largely failed to achieve durable³²
³³responses, the significantly increased neoantigen burden at recurrence is evidently³³
³⁴not sufficient on its own to render immunotherapy effective. Other factors besides³⁴
³⁵neoantigen burden, for example the unique immunosuppressive environment of as-³⁵
³⁶cites, will likely need to be overcome for immunotherapy to be effective in this³⁶
³⁷disease [ref].³⁷

³⁸Detection of the cyclophosphamide and cisplatin signatures from the *G. Gallus*³⁸
³⁹experiments showed some correlation with clinical treatment, whereas the *G. Gallus*³⁹
⁴⁰etoposide and *C. Elegans* cisplatin signatures were not detected in chemotherapy-⁴⁰
⁴¹exposed samples. Many treated samples showed no chemotherapy signatures; when⁴¹
⁴²chemotherapy signatures were detected, they were found at levels close to the 6%⁴²
⁴³detection threshold. In the case of cyclophosphamide, the deconvolution of all mu-⁴³
⁴⁴tations from all samples identified the signature in 4/10 samples treated with cy-⁴⁴
⁴⁵clophosphamide and 4/104 unexposed samples. However, when we focused on muta-⁴⁵
⁴⁶tions detected uniquely in the post-treatment paired samples, 6/8 samples exposed⁴⁶

only to non-cyclophosphamide chemotherapies exhibited the signature. As it was rarely detected in pre-treatment samples, we suggest that the cyclophosphamide signature present in these post-treatment samples may reflect the effect of other chemotherapy, such as carboplatin, paclitaxel, doxorubicin, or gemcitabine. Analysis of the paired pre- and post-treatment samples indicated that the *G. Gallus* cisplatin signature was specific for cisplatin rather than carboplatin exposure, suggesting that carboplatin may induce fewer mutations or mutations with a different signature than cisplatin. The *C. Elegans* cisplatin signature may be less accurate than the *G. Gallus* cisplatin signature because it was derived from fewer mutations (784 vs. 2633) and from experiments of *C. Elegans* in various knockout backgrounds, which may not be relevant to these clinical samples. While only SNVs are accounted for by mutational signatures, an increase in indels and cisplatin-associated dinucleotide variants was observed in relapse/treated samples, but these variants remained relatively rare and generated less than 13% of the predicted neoantigen burden in every sample. Etoposide-induced mutations may be difficult to detect because in the *G. Gallus* experiments they occurred at a more uniform distribution of mutational contexts and at a much lower overall rate than mutations induced by cisplatin or cyclophosphamide. Importantly, only one patient in this cohort received etoposide.

The observed association between mutational signatures and clinical exposures gives some confidence that our analysis captures the effect of chemotherapy, but, as the preclinical signatures may differ from actual effects in patients, chemotherapy-induced mutations could erroneously be attributed to non-chemotherapy signatures. This would result in an underestimation of the impact of chemotherapy. We note, however, that the fraction of mutations that either match a COSMIC signature other than (1), (3), or (8) or do not match any COSMIC or chemotherapy signature (a quantity indicated as “Other SNV” in Figure 3), is no greater in the treated vs. untreated samples. This provides evidence against the possibility that many chemotherapy-induced mutations are unaccounted for in our analysis because they do not match any signature or spuriously match extraneous COSMIC signatures. However, we cannot exclude the possibility that chemotherapy-induced mutations could be erroneously attributed to COSMIC Signatures (1), (3), or (8). Experiments using human cell lines exposed to the range of chemotherapies used in recurrent ovarian cancer may be needed to fully address this question. Alternatively, *de novo* identification of chemotherapy signatures from clinical samples may become feasible as more post-treatment samples are sequenced. Tumor types other than HGSC may more readily show detectable levels of chemotherapy-induced mutations to inform such a deconvolution. A striking contrast our results is a report of NACT temozolomide-treated glioma, in which it was reported that over 98% of mutations detectable with bulk sequencing in some samples were attributable to temozolomide [5]. Whether this difference is due to the drug used or disease biology requires further study.

We predicted a median of 64 (50–75) expressed MHC I neoantigens across all samples in the cohort, significantly more than the median of 6 recently reported by Martin et al. in this disease [25]. However, Martin et al. did not consider indels, MNVs, or multiple neoantigens that can result from the same missense mutation,

¹used a 100nm instead of 500nm MHC I binding threshold, used predominantly lower¹
²quality (50bp) sequencing, and only explicitly considered HLA-A alleles. Predicted²
³neoantigen burden is best considered a relative measure of tumor foreignness, not³
⁴an absolute quantity readily comparable across studies.⁴

⁵ This study has several important limitations. As it is based on bulk DNA sequenc-⁵
⁶ing of heterogeneous clinical samples, the analysis is limited to neoantigens arising⁶
⁷from mutations that are present in at least 5-10% of the cells in a sample. Data⁷
⁸from Patch et al. suggests that even late-stage disease remains polyclonal, therefore⁸
⁹potentially obscuring the impact of chemotherapy on the tumor genome. Single-⁹
¹⁰cell sequencing may be required to observe most chemotherapy-induced mutations,¹⁰
¹¹especially in the neoadjuvant setting. While we may have been unable to detect¹¹
¹²subclonal mutations due to the depth of whole genome sequencing, it is expected¹²
¹³that such clones would be unable to trigger an anti-tumor immune response that is¹³
¹⁴effective against the bulk of the tumor [26]. As previously mentioned, the possibil-¹⁴
¹⁵ity that chemotherapy-induced mutations are spuriously attributed to mutational¹⁵
¹⁶signatures already operative in the primary tissue cannot formally be excluded. A¹⁶
¹⁷further limitation is that this study does not consider neoantigens resulting from¹⁷
¹⁸structural rearrangements such as gene fusions. Finally, this study relies on only 35¹⁸
¹⁹post-chemotherapy samples.¹⁹

²¹Conclusion²¹

²²In this study, we demonstrate a method for connecting mutational signatures ex-²²
²³tracted from studies of mutagen exposure in preclinical models with computa-²³
²⁴tionally predicted neoantigen burden in clinical samples. We found that relapsed high²⁴
²⁵grade serous ovarian cancer tumors harbor nearly double the predicted expressed²⁵
²⁶neoantigen burden of primary samples, and that cisplatin and cyclophosphamide²⁶
²⁷chemotherapy treatments account for a small but detectable part of this effect.²⁷
²⁸The mutagenic processes responsible for most mutations at relapse are similar to²⁸
²⁹those operative in primary tumors, with COSMIC *Signature (3) BRCA*, *Signature*²⁹
³⁰*(1) Age*, and *Signature (8) Unknown etiology* accounting for most mutations and³⁰
³¹predicted neoantigens both before and after chemotherapy.³¹

Figures

Additional Files

Additional file 1 — Samples

Sample identifiers, basic clinical information, specimen purities, mutation and neoantigen burden, contributions of major mutational signatures to mutations and neoantigens, and chemotherapy treatments.

Additional file 2 — Mutations

Somatic variants and their read counts, predicted effects, and resulting neoantigens.

Figure 1 Detected mutational signatures for donor-matched primary/untreated and relapse/treated samples. Signatures detected in the pre-treatment samples. The first four signatures were extracted from reports of a *G. gallus* cell line and *C. Elegans* after exposure to chemotherapy, and the rest are COSMIC curated signatures. COSMIC signature numbers are shown in parentheses, and the associated mutagenic process is indicated when known. Signatures not shown were undetected in these samples. (Bottom) Clinical treatments and detected signatures for the mutations unique to the post-treatment samples (those with no evidence in the matched pre-treatment sample). Cases where a chemotherapy signature is detected are annotated with a (*) if the patient received the associated drug and a (?) otherwise.

Figure 2 Stratified comparison of mutation and neoantigen burden of chemotherapy-treated and untreated samples. Mutations (upper left), neoantigens (upper right), and expressed neoantigens by count (lower left) and as a percent of total neoantigens (lower right) are shown for primary/untreated samples (blue; solid tumor n=75, ascites n=4), primary/treated samples (green; solid tumor n=5), and relapse/treated samples (red; solid tumor n=6 samples from 3 patients, ascites n=24 samples from 21 patients). The shaded boxes indicate the interquartile region and the median line, where multiple samples of the same type from the same patient have been reweighted so that each patient contributes equally. Points indicate individual samples.

Figure 3 Contribution of key SNV signatures, MNVs, and indels on mutations (left), neoantigens (center), and expressed neoantigens (right). The *Chemo* category combines the contributions from the chemotherapy signatures (cisplatin, cyclophosphamide, and etoposide). COSMIC signature numbers are in parentheses. The *Other SNV* category represents SNVs not accounted for by the signatures shown. Bars give the mean, and points indicate individual samples.

Additional file 3 — HLA types

Patient HLA types.

Additional file 4 — Mutational signatures

COSMIC signatures and extracted chemotherapy signatures.

Additional file 5 — Signature deconvolutions

Results of mutational signature deconvolution, including a separate analysis of mutations unique to the treated paired samples

Additional file 6 — Shared neoantigens

Neoantigens predicted for multiple patients

Additional file 7 — Supplemental figures

Supplemental figures S1–S7.
