Abstract

Background: Patients with highly mutated tumors, such as melanoma or smoking-related lung cancer, have higher rates of response to immune checkpoint blockade therapy, perhaps due to increased neoantigen expression. Many chemotherapies including platinum compounds are known to be mutagenic, but the impact of standard treatment protocols on mutational burden and resulting neoantigen expression in most human cancers is unknown.

Methods: We sought to quantify the effect of chemotherapy treatment on computationally predicted neoantigen expression for high grade serous ovarian carcinoma (HGSC) patients in the Australian Ovarian Cancer Study. This cohort includes 79 primary untreated samples, five primary samples collected after neoadjuvant chemotherapy, and 30 chemotherapy-exposed relapse samples, 14 of which are matched with an untreated sample from the same patient. Our approach integrates tumor whole genome and RNA sequencing with class I MHC binding prediction and mutational signatures of chemotherapy exposure extracted from preclinical studies of chemotherapy-exposed *C. Elegans* and *G. Gallus* cells.

Results: In an analysis stratified by tissue type, relapse samples collected after chemotherapy harbored a median of 78% more expressed neoantigens than untreated primary samples, a figure that combines the effects of chemotherapy and other mutagenic processes operative during relapse. Neoadjuvant-treated primary samples showed no detectable increase over untreated samples. The contribution from chemotherapy-associated signatures was small, accounting for a mean of 5% (range 0–16) of the expressed neoantigen burden in relapse samples. In both treated and untreated samples, most neoantigens were attributed to COSMIC *Signature (3)*, associated with BRCA disruption, *Signature (1)*, associated with a slow mutagenic process active in healthy tissue, and *Signature (8)*, of unknown etiology.

Conclusion: Relapsed HGSC tumors harbor nearly double the predicted expressed neoantigen burden of primary samples, but mutations directly attributable to chemotherapy signatures account for only a small part of this increase. The mutagenic processes responsible for most neoantigens are similar between primary and relapse samples. Our analyses are based on sequencing of bulk samples and do not account for neoantigens present in small populations of cells.

Keywords: neoantigen; mutational signature; chemotherapy

Background

Many chemotherapies including platinum compounds [1], cyclophosphamide [2], and etoposide [3] exert their effect through DNA damage, and recent studies

Table 1 Number of samples by tissue and chemotherapy exposure. Parentheses indicate chemotherapy-treated samples with a patient-matched primary/untreated sample.

have found evidence for chemotherapy-induced mutations in post-treatment acute myeloid leukaemia [4], glioma [5], and esophageal adenocarcinoma [6]. Successful development of immune checkpoint-mediated therapy [7] has focused attention on the importance of T cell responses to somatic mutations in coding genes that generate neoantigens [8]. Studies based on bulk-sequencing of tumor samples followed by computational peptide-class I MHC affinity prediction [9] have suggested that tumors with more mutations and predicted mutant MHC I peptide ligands are more likely to respond to checkpoint blockade immunotherapy [10, 11]. Ovarian cancers fall into an intermediate group of solid tumors in terms of mutational load present in pre-treatment surgical samples [12]. However, the effect of standard chemotherapy regimes on tumor mutation burden and resulting neoantigen expression in ovarian cancer is poorly understood.

Investigators associated with the Australian Ovarian Cancer Study (AOCS) performed whole genome and RNA sequencing of 79 pre-treatment and 35 post-treatment cancer samples from 92 HGSC patients, including 12 patients with both pre- and post-treatment samples [13]. The samples were obtained from solid tissue resections, autopsies, and ascites drained to relieve abdominal distension. Treatment regimes varied but primary treatment always included platinum-based chemotherapy. In their analysis, Patch et al. reported that post-treatment samples harbored more somatic mutations than pre-treatment samples and exhibited evidence of chemotherapy-associated mutations. Here we extend these results by quantifying the mutations and predicted neoantigens attributable to chemotherapy-associated mutational signatures. We find that, while neoantigen expression increases after treatment and relapse, only a small part of the increase is due to mutations associated with chemotherapy signatures.

Methods

Clinical sample information

We grouped the AOCS samples into three sets — “primary/untreated,” “primary/treated,” and “relapse/treated” — according to collection time point and chemotherapy exposure (Table 1). The primary/untreated group consists of 75 primary debulking surgical samples and 4 samples of drained ascites. The primary/treated group consists of 5 primary debulking surgical samples obtained from patients pretreated with chemotherapy prior to surgery (neoadjuvant chemotherapy). The relapse/treated group consists of 24 relapse or recurrence ascites samples,

5 metastatic samples obtained in autopsies of two patients, and 1 solid tissue relapse¹
 surgical sample, all of which were obtained after prior exposure to one or more lines²
 of chemotherapy. In summary, these groupings yield 79 primary/untreated samples,³
 5 primary/treated samples, and 30 relapse/treated samples. Specimen and clinical⁴
 information for each sample is listed in Additional File 1.⁵

Independent of treatment, ascites samples trend toward more detected mutations,⁶
 perhaps due to increased intermixing of clones. We therefore stratified by tissue type⁷
 (solid tumor or ascites) when comparing the mutation and neoantigen burdens of⁸
 pre- and post-treatment samples. As some patients provided multiple samples of⁹
 the same type, we reweighted the samples so each patient contributes equally to¹⁰
 these comparisons.¹¹

13 Mutation calls

We analyzed the mutation calls published by Patch *et al.* [13] (Additional File 2).¹⁴
 DNA and RNA sequencing reads were downloaded from the European Genome-¹⁵
 phenome Archive under accession EGAD00001000877. Adjacent SNVs from the¹⁶
 same patient were combined to form multinucleotide variants (MNVs).¹⁷

We considered a mutation to be present in a sample if it was called for the patient¹⁸
 and more than 5 percent of the overlapping reads and at least 6 reads total supported¹⁹
 the alternate allele. We considered a mutation to be expressed if there were 3 or²⁰
 more RNA reads supporting the alternate allele. In the analysis of paired pre- and²¹
 post-treatment samples from the same donors, we defined a mutation as unique to²²
 the post-treatment sample if the pre-treatment sample contained greater than 30²³
 reads coverage and no variant reads at the site.²⁴

26 Variant annotation, HLA typing, and MHC binding prediction

Protein coding effects were predicted using Varcode (manuscript in preparation,²⁷
<https://github.com/hammerlab/varcode>). All transcripts overlapping each muta-²⁸
 tion were considered, and the transcript with the most disruptive effect was selected²⁹
 using a prioritization similar to other tools (from highest priority: frameshift, loss of³⁰
 stop codon, insertion or deletion, substitution). In the case of frameshift mutations,³¹
 all downstream peptides generated up to a stop codon were considered potential³²
 neoantigens.³³

HLA typing was performed using a consensus of seq2HLA [14] and OptiType [15]³⁴
 across the samples for each patient (Additional File 3).³⁵

Class I MHC binding predictions were performed for peptides of length 8–11 using³⁶
 NetMHCpan 2.8 [16] with default arguments (predicted neoantigens are listed in³⁷
 Additional File 2).³⁸

40 Mutational signatures

The use of mutational signatures is necessary because it is not possible to dis-⁴¹
 tinguish chemotherapy-induced mutations from temporal effects when comparing⁴²
 primary and relapse samples by mutation count alone. A mutational signature as-⁴³
 cribes a probability to each of the 96 possible single-nucleotide variants, where a⁴⁴
 variant is defined by its reference base pair, alternate base pair, and base pairs im-⁴⁵
 mediately adjacent to the mutation. Signatures have been associated with exposure⁴⁶

to particular mutagens, age related DNA changes, and disruption of DNA damage¹
 repair pathways due to somatic mutations or germline risk variants in melanoma,²
 breast, lung and other cancers [17], and provide a means of identifying the con-³
 tribution that chemotherapy may make to the mutations seen in post-treatment⁴
 samples. For example, the chemotherapy temozolomide has been shown to induce⁵
 mutations consisting predominantly of $C \rightarrow T$ (equivalently, $G \rightarrow A$) transitions⁶
 at CpC and CpT dinucleotides [5]. To perform deconvolution, the single nucleotide⁷
 variants (SNVs) observed in a sample are tabulated by trinucleotide context, and⁸
 a combination of signatures, each corresponding to a mutagenic process, is found⁹
 that best explains the observed counts. Mutational signatures may be discovered *de*¹⁰
novo from large cancer sequencing projects but for smaller studies it is preferable¹¹
 to deconvolve using known signatures [18].¹²

The Catalogue Of Somatic Mutations In Cancer (COSMIC) Signature Resource¹³
 curates 30 signatures discovered in a pan-cancer analysis of untreated primary tissue¹⁴
 samples. While signatures for exposure to the carboplatin/paclitaxel combination¹⁵
 that is standard first line therapy in ovarian cancer have not been established,¹⁶
 two recent reports provide data on mutations detected in cisplatin-exposed *C. El*-¹⁷
egans [19] and a *G. Gallus* cell line exposed to several chemotherapies including¹⁸
 cisplatin, chyclophosphamide, and etoposide [20]. As cisplatin is thought to induce¹⁹
 the same DNA adducts as carboplatin, we reasoned that the mutational signatures²⁰
 of these related compounds are likely similar [21]. In the AOCS cohort, 28 patients²¹
 with post-treatment samples were treated with carboplatin, four with cisplatin,²²
 eight with cyclophosphamide, and one with etoposide.²³

From the SNVs identified in the animal models, we defined two signatures for²⁴
 cisplatin, a signature for cyclophosphamide, and a signature for etoposide (Fig-²⁵
 ures S1 and S2). As both studies sequenced replicates of chemotherapy-treated²⁶
 and untreated (control) samples, identifying a mutational signature associated with²⁷
 treatment required splitting the mutations observed in the treated group into back-²⁸
 ground and treatment effects. We did this using a Bayesian model for each study²⁹
 and chemotherapy drug separately.³⁰

Let $C_{i,j}$ be the number of mutations observed in experiment i for mutational trin-³¹
 ucleotide context $0 \leq j < 96$. Let $t_i \in \{0, 1\}$ be 1 if the treatment was administered³²
 in experiment i and 0 if it was a control. We estimate the number of mutations³³
 in each context arising due to background (non-treatment) processes B_j and the³⁴
 number due to treatment T_j according to the model:³⁵

$$C_{i,j} \sim \text{Poisson}(B_j + t_i T_j)$$

We fit this model using Stan [22] with a uniform (improper) prior on the entries³⁸
 of B and T . The treatment-associated mutational signature N was calculated from³⁹
 a point estimate of T as:⁴⁰

$$N_j = \left(\frac{T_j}{\sum_{j'} T_{j'}} \right) \left(\frac{h_j}{m_j} \right)$$

where h_j and m_j are the number of times the reference trinucleotide j occurs in⁴⁵
 the human and preclinical model (*C. Elegans* or *G. Gallus*) genomes, respectively.⁴⁶

¹ Signature deconvolution was performed with the deconstructSigs[18] package us-¹
²ing the 30 mutational signatures curated by COSMIC [23] extended to include the²
³putative chemotherapy-associated signatures (Additional Files 4 and 5). When es-³
⁴tablishing whether a signature was detected in a sample, we applied the 6% cutoff⁴
⁵recommended by the authors of the deconstructSigs package. Signatures assigned⁵
⁶weights less than this threshold in a sample were considered undetected.⁶

⁷ To estimate the number of SNVs and neoantigens generated by a signature, for⁷
⁸each mutation in the sample we calculated the posterior probability that the sig-⁸
⁹nature generated the mutation, as described below. The sum of these probabilities⁹
¹⁰gives the expected number of SNVs attributable to each signature. For neoantigens,¹⁰
¹¹we weighted the terms of this sum by the number of neoantigens generated by each¹¹
¹²mutation.¹²

¹³ Suppose a mutation occurs in context j and sample i . We calculate $\Pr[s | j]$, the¹³
¹⁴probability that signature s gave rise to this mutation, using Bayes' rule:¹⁴

$$\Pr[s | j] = \frac{\Pr[j | s] \Pr[s]}{\sum_{s'} \Pr[j | s'] \Pr[s']} = \frac{H_{s,j} D_{i,s}}{\sum_{s'} H_{s',j} D_{i,s'}}$$

¹⁸ where $D_{i,s}$ is the result matrix from deconstructSigs, giving the contribution of¹⁸
¹⁹signature s to sample i , and $H_{s,j}$ is the weight for signature s on mutational context¹⁹
²⁰ j . For each chemotherapy-associated signature, $H_{s,j}$ is given by N_j above. For the²⁰
²¹other signatures it is defined in the COSMIC Signature Resource.²¹

²² For treated samples with a pre-treatment sample available from the same patient,²²
²³we deconvolved signatures for both the full set of mutations and for the mutations²³
²⁴detected only after treatment. When calculating $\Pr[s | j]$ for these samples, for each²⁴
²⁵mutation we selected the appropriate deconvolution matrix $D_{i,s}$ based on whether²⁵
²⁶the mutation was unique to the post-treatment sample.²⁶

²⁸ Results ²⁸

²⁹ Cisplatin and cyclophosphamide mutational signatures correlate with clinical treatment ²⁹

³⁰ We identified mutational signatures for cisplatin, cyclophosphamide, and etoposide³⁰
³¹from the *G. Gallus* cell line data (Figure S1), as well as a second cisplatin signature³¹
³²from experiments in *C. Elegans* (Figure S2). The two cisplatin signatures were not³²
³³identical. Both signatures placed most probability mass on $C \rightarrow A$ mutations, but³³
³⁴differed in preference for the nucleotides adjacent to the mutation. The *G. Gallus*³⁴
³⁵signature was relatively indifferent to the 5' base and favored a 3' cytosine, whereas³⁵
³⁶the *C. Elegans* signature was specific for a 5' cytosine and a 3' pyrimidine. The³⁶
³⁷*G. Gallus* cisplatin signature was closest in cosine distance to COSMIC Signature³⁷
³⁸(24) Aflatoxin, Signature (4) Smoking, and Signature (29) Chewing tobacco, all as-³⁸
³⁹sociated with guanine adducts. The *C. Elegans* cisplatin signature was similar to³⁹
⁴⁰Signature (4) Smoking, Signature (20) Mismatch repair, and Signature (14) Un-⁴⁰
⁴¹known. The *G. Gallus* cyclophosphamide signature favored $T \rightarrow A$ and $C \rightarrow T$ ⁴¹
⁴²mutations and was most similar to COSMIC Signatures (25), (8), and (5), all of⁴²
⁴³unknown etiology. The *G. Gallus* etoposide signature distributed probability mass⁴³
⁴⁴nearly uniformly across mutation contexts and was most similar to COSMIC Sig-⁴⁴
⁴⁵nature (5) Unknown, Signature (3) BRCA, and Signature (16) Unknown. Overall,⁴⁵
⁴⁶the chemotherapy signatures were no closer to any COSMIC signatures than the⁴⁶

¹two most similar COSMIC signatures (*Signature (12) Unknown* and *Signature (26)*¹
²*Mismatch repair*) are to each other, suggesting that deconvolution could in principle²
³distinguish their contributions.³

⁴ We performed signature deconvolution on each sample's SNVs (top and middle⁴
⁵of Figures S3 and S4). Detection of the cyclophosphamide signature at the 6%⁵
⁶threshold was associated with clinical cyclophosphamide treatment (Bonferroni-⁶
⁷corrected Fischer's exact test $p = 0.004$), occurring in 4/10 samples taken after cy-⁷
⁸clophosphamide treatment, 2/79 pre-treatment samples, and 2/25 samples exposed⁸
⁹to chemotherapies other than cyclophosphamide. In contrast, the two cisplatin sig-⁹
¹⁰natures were found in no samples, and the etoposide signature was found only in¹⁰
¹¹four pre-treatment samples.¹¹

¹² For better sensitivity, we next focused on the 14 relapse/treated samples from¹²
¹³the 12 patients with both pre- and post-treatment samples. For each patient, we¹³
¹⁴extracted the mutations that had evidence exclusively in the treated samples. Of¹⁴
¹⁵206,766 SNVs in the post-treatment samples for these patients, 93,986 (45%) satis-¹⁵
¹⁶fied our filter and were subjected to signature deconvolution (Figure 1, bottom of¹⁶
¹⁷Figures S3 and S4). Within this subgroup, the *G. gallus* cisplatin signature was iden-¹⁷
¹⁸tified only in the two samples taken after cisplatin therapy, a significant association¹⁸
¹⁹($p = 0.04$). The *C. Elegans* cisplatin signature was detected in no samples, and the¹⁹
²⁰cyclophosphamide signature was detected in 3/6 cyclophosphamide-treated sam-²⁰
²¹ples, but, unexpectedly, also in 6/8 non-cyclophosphamide-treated samples. These²¹
²²included the two post-treatment samples in which the signature was detected in the²²
²³earlier analysis plus four additional samples. COSMIC *Signature (3) BRCA* and²³
²⁴*Signature (8) Unknown etiology* were detected in 14/14 and 9/14 post-treatment²⁴
²⁵samples, respectively, but *Signature (1) Age* was absent, consistent with its associ-²⁵
²⁶ation with a slow mutagenic process operative before oncogenesis.²⁶

²⁷ In summary, the mutational signatures for cisplatin and cyclophosphamide ex-²⁷
²⁸tracted from experiments of a *G. Gallus* cell line showed significant but inexact²⁸
²⁹associations with clinical chemotherapy exposure.²⁹

³⁰Neoantigen burden increases at relapse³⁰

³¹ Across the cohort, we identified 17,689 mutated peptides predicted to bind autol-³¹
³²ogous MHC class I with affinity 500nm or tighter [24]. All but 21 (0.12%) of these³²
³³predicted neoantigens were private to a single patient (shared neoantigens are listed³³
³⁴in Additional File 6).³⁴

³⁵ Relapse/treated samples harbored a median 78% more expressed neoantigens than³⁵
³⁶primary/untreated samples (weighted mean of stratum-specific estimates). Specif-³⁶
³⁷ically, solid tissue relapse samples harbored a median of 71% (bootstrap 95% CI³⁷
³⁸23–123) more mutations, 107% (32–187) more neoantigens, and 72% (16–137) more³⁸
³⁹expressed neoantigens than primary/untreated solid tissue samples (Figure 2), all³⁹
⁴⁰significant increases (Mann-Whitney $p < 0.05$ for each of the three tests). A sim-⁴⁰
⁴¹ilar trend was observed for ascites samples. Relapse/treated ascites samples har-⁴¹
⁴²bored 32% (14–51), 55% (10–118), and 83% (22–178) more mutations, neoanti-⁴²
⁴³gens, and expressed neoantigens than primary/untreated ascites samples, respec-⁴³
⁴⁴tively ($p = 0.07, 0.10, 0.05$ for the three tests). This trend was also apparent in⁴⁴
⁴⁵a comparison of paired samples from the same donors (Figure S5). Among re-⁴⁵
⁴⁶lapse/treated samples, the number of lines of chemotherapy and the time elapsed⁴⁶

¹between chemotherapy and sample acquisition did not show a significant correlation¹
²(Figure S6). TODO²
³In contrast, primary/treated samples, which were exposed to neoadjuvant³
⁴chemotherapy (NACT) prior to surgery, did not exhibit increased numbers of muta-⁴
⁵tions, neoantigens, or expressed neoantigens, and in fact trended toward decreased⁵
⁶expressed neoantigen burden. The five primary/treated samples, all from solid tis-⁶
⁷sue resections, harbored a median of 16 (9–89) expressed neoantigens compared to⁷
⁸the median of 44 (39–60) observed in primary/untreated solid tissue samples, due to⁸
⁹both fewer neoantigens in the DNA (median of 85 (36–306) vs. 130 (108–150)) and a⁹
¹⁰lower rate of expression (median 19 (14–37) vs. 39 (36–42) percent of neoantigens).¹⁰
¹¹This trend did not reach significance (Mann-Whitney $p = 0.08$), and will require¹¹
¹²larger cohorts to assess.¹²

¹³Chemotherapy signatures weakly contribute to neoantigen burden at relapse¹⁴

¹⁵While we cannot determine with certainty whether any particular mutation was¹⁵
¹⁶chemotherapy-induced, we can estimate the fraction of mutations and neoantigens¹⁶
¹⁷attributable to each signature in a sample (Figures 3 and S7).¹⁷
¹⁸Similarly to results reported by Patch et al., the most prevalent mutational signa-¹⁸
¹⁹tures in this cohort were COSMIC *Signature (3)*, associated with BRCA disruption,¹⁹
²⁰*Signature (8)*, of unknown etiology, and *Signature (1)*, associated with spontaneous²⁰
²¹deamination of 5-methylcytosine, a slow process active in healthy tissue that cor-²¹
²²relates with age (Figure S3 top and middle). These signatures together accounted²²
²³for a median of 67% (95% CI 66–69) of mutations, 58% (56–61) of neoantigens, and²³
²⁴68% (67–71) expressed neoantigens across samples. These rates did not substantially²⁴
²⁵differ with chemotherapy treatment.²⁵

²⁶The chemotherapy signatures accounted for a small but detectable part of the²⁶
²⁷increased neoantigen burden of relapse samples. In primary/untreated samples,²⁷
²⁸which indicate the background rate of chance attribution, chemotherapy muta-²⁸
²⁹tional signatures accounted for a mean of 2% of the mutations (range 0–8), 2%²⁹
³⁰(0–7) of the neoantigens, and 2% (0–8) of the expressed neoantigens. In each of the³⁰
³¹five primary/treated samples, less than 1% of the mutation, neoantigen, and ex-³¹
³²pressed neoantigen burdens were attributed to chemotherapy signatures. For the re-³²
³³lapse/treated samples, chemotherapy signatures accounted for a mean of 6% (range³³
³⁴0–21) of the mutations, 5% (0–15) of the neoantigens, and 5% (0–16) of the ex-³⁴
³⁵pressed neoantigens. The highest attribution to chemotherapy signatures occurred³⁵
³⁶in sample AOCS-092-3-3, a relapse/treated sample from a patient who received five³⁶
³⁷lines of platinum chemotherapy and eight distinct chemotherapeutic agents, the³⁷
³⁸most in the cohort. For this sample, 21% (or approximately 3,200 of 15,491) of³⁸
³⁹the SNVs, 15% (9 of 61) of the neoantigens, and 16% (5 of 30) of the expressed³⁹
⁴⁰neoantigens were attributed to chemotherapy signatures.⁴⁰

⁴¹Signature deconvolution considers only SNVs, but studies of platinum-induced⁴¹
⁴²mutations have also reported increases in the rate of dinucleotide variants and indels.⁴²
⁴³Indeed, we observed more MNVs overall and specifically the platinum-associated⁴³
⁴⁴MNVs $CT \rightarrow AC$ and $CA \rightarrow AC$ reported by Meier et al. [19] in treated patients⁴⁴
⁴⁵in both absolute count and as a fraction of mutational burden ($p < 10^{-6}$ for all⁴⁵
⁴⁶tests). Sample AOCS-092-3-3, previously found to have the most chemotherapy-⁴⁶
⁴⁶signature SNVs, also had the most platinum-associated dinucleotide variants and⁴⁶

¹the second-most MNVs overall. This sample harbored 59 $CT \rightarrow AC$ or $CA \rightarrow AC$ ¹
²mutations, compared to a mean of 3.2 (2.2–4.4) across all samples. Treated samples²
³also harbored more indels in terms of absolute count ($p = 10^{-4}$). Overall, while³
⁴MNVs and indels generate more neoantigens per mutation than SNVs, they are⁴
⁵rare, comprising less than 3% of the mutational burden and 13% of the neoantigens⁵
⁶in every sample (Figure 3), making it unlikely that chemotherapy-induced MNVs⁶
⁷and indels have a large impact on neoantigen burden.⁷

⁹Discussion⁹

¹⁰In this analysis of neoantigens predicted from DNA and RNA sequencing of ovarian¹⁰
¹¹cancer tumors and ascites samples, relapse samples obtained after chemotherapy¹¹
¹²exposure had a median of 78% more expressed neoantigens than untreated primary¹²
¹³samples. However, putative chemotherapy mutational signatures accounted for no¹³
¹⁴more than 16% of the expressed neoantigen burden in any sample. Most of the¹⁴
¹⁵increase was instead attributable to mutagenic processes already at work in the pri-¹⁵
¹⁶mary samples, including COSMIC *Signature (3) BRCA* and *Signature (8) Unknown*¹⁶
¹⁷*etiology*.¹⁷

¹⁸These results are consistent with a model in which outgrowth of a subclone follow-¹⁸
¹⁹ing surgery and adjuvant chemotherapy raises many mutations previously confined¹⁹
²⁰to a small number of cells to population levels detectable by bulk sequencing. In such²⁰
²¹a model, it is not the direct mutagenic effect of the treatment that raises the mu-²¹
²²tational burden, but rather the indirect effect of creating a population bottleneck.²²
²³Consistent with this interpretation, NACT-treated samples, which were exposed to²³
²⁴chemotherapy as large tumors and for a short duration (typically 3 cycles), did not²⁴
²⁵show increased mutation or neoantigen burden over untreated samples and had very²⁵
²⁶few mutations attributed to chemotherapy.²⁶

²⁷Clinically, while recurrent tumors may be expected to harbor more potential²⁷
²⁸neoantigens, our results suggest it would be difficult to rationally increase neoanti-²⁸
²⁹gen burden through manipulation of chemotherapy dosage, as even the most heavily²⁹
³⁰treated patients in this cohort show only a modest number chemotherapy-induced³⁰
³¹neoantigens. As immunotherapy trials in ovarian cancer have been in the setting of³¹
³²heavily pre-treated recurrent disease, the significantly increased neoantigen burden³²
³³at recurrence is demonstrably not sufficient on its own to render immunotherapy³³
³⁴effective. Other factors besides neoantigen burden, for example the unique immuno-³⁴
³⁵suppressive environment of ascites, will likely need to be overcome for immunother-³⁵
³⁶apy to be effective in this disease [ref].³⁶

³⁷Detection of the cyclophosphamide and cisplatin signatures from the *G. Gallus*³⁷
³⁸experiments showed some correlation with clinical treatment, whereas the *G. Gallus*³⁸
³⁹etoposide and *C. Elegans* cisplatin signatures were not detected in chemotherapy-³⁹
⁴⁰exposed samples. Many treated samples showed no chemotherapy signatures; when⁴⁰
⁴¹chemotherapy signatures were detected, they were found at levels close to the 6%⁴¹
⁴²detection threshold. In the case of cyclophosphamide, the deconvolution of all mu-⁴²
⁴³tations from all samples identified the signature in 4/10 samples treated with cy-⁴³
⁴⁴clophosphamide and 4/104 unexposed samples. However, when we focused on muta-⁴⁴
⁴⁵tions detected uniquely in the post-treatment paired samples, 6/8 samples exposed⁴⁵
⁴⁶only to non-cyclophosphamide chemotherapies exhibited the signature. As it was⁴⁶

¹rarely detected in pre-treatment samples, we suggest that the cyclophosphamide¹
²signature present in these post-treatment samples may reflect the effect of other²
³chemotherapy, such as carboplatin, paclitaxel, doxorubicin, or gemcitabine. Anal-³
⁴ysis of the paired pre- and post-treatment samples indicated that the *G. Gallus*⁴
⁵cisplatin signature was specific for cisplatin rather than carboplatin exposure, sug-⁵
⁶gesting that carboplatin may induce fewer mutations or mutations with a different⁶
⁷signature than cisplatin. The *C. Elegans* cisplatin signature may be less accurate⁷
⁸than the *G. Gallus* cisplatin signature because it was derived from fewer mutations⁸
⁹(784 vs. 2633) and from experiments of *C. Elegans* in various knockout backgrounds,⁹
¹⁰which may not be relevant to these clinical samples. While only SNVs are ac-¹⁰
¹¹counted for by mutational signatures, an increase in indels and cisplatin-associated¹¹
¹²dinucleotide variants was observed in relapse/treated samples, but these variants¹²
¹³remained relatively rare and generated less than 13% of the predicted neoantigen¹³
¹⁴burden in every sample. Etoposide-induced mutations may be difficult to detect¹⁴
¹⁵because in the *G. Gallus* experiments they occurred at a more uniform distribution¹⁵
¹⁶of mutational contexts and at a much lower overall rate than mutations induced by¹⁶
¹⁷cisplatin or cyclophosphamide. Importantly, only one patient in this cohort received¹⁷
¹⁸etoposide.¹⁸

¹⁹The observed association between mutational signatures and clinical exposures¹⁹
²⁰gives some confidence that our analysis captures the effect of chemotherapy, but, as²⁰
²¹the preclinical signatures may differ from actual effects in patients, chemotherapy-²¹
²²induced mutations could be erroneously attributed to non-chemotherapy signatures.²²
²³This would result in an underestimation of the impact of chemotherapy. We note,²³
²⁴however, that the fraction of mutations that either match a COSMIC signature²⁴
²⁵other than (1), (3), or (8) or do not match any COSMIC or chemotherapy signature²⁵
²⁶(a quantity indicated as “Other SNV” in Figure 3), is no greater in the treated²⁶
²⁷vs. untreated samples. This provides evidence against the possibility that many²⁷
²⁸chemotherapy-induced mutations are unaccounted for in our analysis because they²⁸
²⁹do not match any signature or spuriously match extraneous COSMIC signatures.²⁹
³⁰However, we cannot exclude the possibility that chemotherapy-induced mutations³⁰
³¹could be erroneously attributed to COSMIC Signatures (1), (3), or (8). Experiments³¹
³²using human cell lines exposed to the range of chemotherapies used in recurrent³²
³³ovarian cancer may be needed to fully address this question.³³

³⁴*De novo* identification of chemotherapy signatures from clinical samples may be-³⁴
³⁵come feasible as more post-treatment samples are sequenced. While our results sug-³⁵
³⁶gest HGSC tumors would mostly contribute relatively few chemotherapy-induced³⁶
³⁷mutations to inform such a deconvolution, other tumor types, including those³⁷
³⁸treated with some of the same chemotherapies as HGSC, may more readily show³⁸
³⁹detectable levels of chemotherapy-induced mutations. A striking example is a study³⁹
⁴⁰of NACT temozolomide-treated glioma, in which it was reported that over 98% of⁴⁰
⁴¹mutations detectable with bulk sequencing in some samples were attributable to⁴¹
⁴²temozolomide [5]. Whether this difference is due to the drug used or disease biology⁴²
⁴³requires further study.⁴³

⁴⁴We predicted a median of 64 (50–75) expressed MHC I neoantigens across all⁴⁴
⁴⁵samples in the cohort, significantly more than the median of 6 recently reported by⁴⁵
⁴⁶Martin et al. in this disease [25]. However, Martin et al. did not consider indels,⁴⁶

¹MNVs, or multiple neoantigens that can result from the same missense mutation,¹
²used a 100nm instead of 500nm MHC I binding threshold, used predominantly lower²
³quality (50bp) sequencing, and only explicitly considered HLA-A alleles. Predicted³
⁴neoantigen burden is best considered a relative measure of tumor foreignness, not⁴
⁵an absolute quantity readily comparable across studies.⁵

⁶ This study has several important limitations. As it is based on bulk DNA sequenc-⁶
⁷ing of heterogeneous clinical samples, the analysis is limited to neoantigens arising⁷
⁸from mutations that are present in at least 5-10% of the cells in a sample. Data⁸
⁹from Patch et al. suggests that even late-stage disease remains polyclonal, therefore⁹
¹⁰potentially obscuring the impact of chemotherapy on the tumor genome. Single-¹⁰
¹¹cell sequencing may therefore be required to observe most chemotherapy-induced¹¹
¹²mutations, especially in the neoadjuvant setting. While we may have been unable¹²
¹³to detect subclonal mutations due to the depth of whole genome sequencing, it is¹³
¹⁴expected that such clones would be unable to trigger an anti-tumor immune re-¹⁴
¹⁵sponse that is effective against the bulk of the tumor [26]. As previously mentioned,¹⁵
¹⁶the possibility that chemotherapy-induced mutations are spuriously attributed to¹⁶
¹⁷mutational signatures already operative in the primary tissue cannot formally be¹⁷
¹⁸excluded. A further limitation is that this study does not consider neoantigens re-¹⁸
¹⁹sulting from structural rearrangements such as gene fusions. Finally, this study¹⁹
²⁰relies on only 35 post-chemotherapy samples.²⁰

²²Conclusion²²

²³ In this study, we demonstrate a method for connecting mutational signatures ex-²³
²⁴tracted from studies of mutagen exposure in preclinical models with computa-²⁴
²⁵tionally predicted neoantigen burden in clinical samples. We found that relapsed high-²⁵
²⁶grade serous ovarian cancer tumors harbor nearly double the predicted expressed²⁶
²⁷neoantigen burden of primary samples, and that cisplatin and cyclophosphamide²⁷
²⁸chemotherapy treatments account for a small but detectable part of this effect.²⁸
²⁹ The mutagenic processes responsible for most mutations at relapse are similar to²⁹
³⁰those operative in primary tumors, with COSMIC *Signature (3) BRCA*, *Signature*³⁰
³¹*(1) Age*, and *Signature (8) Unknown etiology* accounting for most mutations and³¹
³²predicted neoantigens both before and after chemotherapy.³²

³⁸Ethics approval and consent to participate³⁸

³⁹ The patients analyzed in this study were treated at hospitals across Australia and were recruited through the³⁹
⁴⁰ Australian Ovarian Cancer Study or through the Gynaecological Oncology Biobank at Westmead Hospital in Sydney.⁴⁰
⁴¹ Four primary refractory cases were obtained from the Hammersmith Hospital Imperial College (London, UK) and the⁴¹
⁴² University of Chicago (Chicago, USA). Ethics board approval was obtained at all institutions for patient recruitment,⁴²
⁴³ sample collection and research studies. Written informed consent was obtained from all participants in this study.⁴³

⁴²Consent for publication⁴²

⁴³ Not applicable.⁴³

⁴⁴Availability of data and materials⁴⁴

⁴⁵ All data generated during this study are included in this published article and its supplementary information files.⁴⁵

⁴⁶ The notebooks used to perform the analyses are available at⁴⁶
⁴⁷ <https://github.com/hammerlab/paper-aocs-chemo-neoantigens>.⁴⁷

Figure 1 Detected mutational signatures for donor-matched primary/untreated and relapse/treated samples. Signatures detected in the pre-treatment samples. The first four signatures were extracted from reports of a *G. gallus* cell line and *C. Elegans* after exposure to chemotherapy, and the rest are COSMIC curated signatures. COSMIC signature numbers are shown in parentheses, and the associated mutagenic process is indicated when known. Signatures not shown were undetected in these samples. (Bottom) Clinical treatments and detected signatures for the mutations unique to the post-treatment samples (those with no evidence in the matched pre-treatment sample). Cases where a chemotherapy signature is detected are annotated with a (*) if the patient received the associated drug and a (?) otherwise.

Figure 2 Stratified comparison of mutation and neoantigen burden of chemotherapy-treated and untreated samples. Mutations (upper left), neoantigens (upper right), and expressed neoantigens by count (lower left) and as a percent of total neoantigens (lower right) are shown for primary/untreated samples (blue; solid tumor n=75, ascites n=4), primary/treated samples (green; solid tumor n=5), and relapse/treated samples (red; solid tumor n=6 samples from 3 patients, ascites n=24 samples from 21 patients). The shaded boxes indicate the interquartile region and the median line, where multiple samples of the same type from the same patient have been reweighted so that each patient contributes equally. Points indicate individual samples.

Figure 3 Contribution of key SNV signatures, MNVs, and indels on mutations (left), neoantigens (center), and expressed neoantigens (right). The *Chemo* category combines the contributions from the chemotherapy signatures (cisplatin, cyclophosphamide, and etoposide). COSMIC signature numbers are in parentheses. The *Other SNV* category represents SNVs not accounted for by the signatures shown. Bars give the mean, and points indicate individual samples.
